Why are relatively poor people not more supportive of redistribution? Evidence from a randomized survey experiment across 10 countries

By Christopher Hoy and Franziska Mager*

We test a key assumption underlying seminal theories about preferences for redistribution, which is that relatively poor people should be the most in favor of redistribution. We conduct a randomized survey experiment with over 30,000 participants across 10 countries, half of whom are informed of their position in the national income distribution. Contrary to prevailing wisdom, people who are told they are relatively poorer than they thought are less concerned about inequality and are not more supportive of redistribution. This finding is consistent with people using their own living standard as a “benchmark” for what they consider acceptable for others.

Social commentators and researchers struggle to explain why, despite growing inequality in many countries around the world, relatively poor people are not more supportive of redistribution (Kuziemko et al. 2014; Roemer 1998; Holland 2018; Frank 2004). For example, a survey of a broadly representative sample of the national population in 44 countries by PEW Research Center shows that relatively poor respondents tend to have similar levels of support for raising taxes on the wealthy to fund programs to help the poor as relatively rich respondents (see Figure 1) (PEW Research Center 2014). This common phenomenon would appear to contradict a key assumption underlying seminal theories of preferences for redistribution, which is poor people should be substantially more supportive of redistribution than rich people (e.g. Meltzer Richard 1981). Recent studies have identified a potential explanation for why this assumption lacks empirical support, which is that relatively poor people do not realize they are in the bottom half of the national income distribution (Gimpelson and Treisman 2018; Bublitz 2016). Surveys across a range of high-income countries have shown that most people tend to think they are positioned around the middle of the national income distribution regardless of whether they are rich or poor (Gimpelson and Treisman 2018). This raises the question, if relatively poor people were made aware of their position in the national income distribution, would they be more concerned about inequality and supportive of redistribution?

We test how informing people they are relatively poorer than they thought impacts their concern about inequality and support for redistribution through a randomized survey experiment with over 30,000 respondents in 10 countries (Australia, India, Mexico, Morocco, Netherlands, Nigeria, South Africa, Spain, the United Kingdom and the United States). Collectively these 10 countries make up around 30 per cent of the global population and represent about 40 per cent of world GDP. This is by far the largest survey experiment about the elasticity of people’s preferences for redistribution to date and the first in multiple middle-income countries. Similar to the approach used by Alesina, Stantcheva and Teso (2018) in a cross-country survey experiment, the sample of respondents is representative of the population with internet access in each country and the data was collected using the survey firms YouGov, IPSOS and RIWI. Respondents in each country were randomly allocated to either receive information about their position in the national income distribution (treatment group) or no information (control group). Prior to the treatment, respondents revealed their perception of the level of national inequality, their preferred level of national inequality and their perceived place in the national income distribution. In addition, they provided information about their demographic characteristics, including household income that was measured using the same approach as Alesina, Stantcheva and Teso (2018). After the treatment, respondents were asked standard questions from the existing literature regarding their views about whether the gap between the rich and poor is too large in their country and whether they think the government is responsible for closing this gap (Alesina, Stantcheva and Teso 2018; ISSP 2009). The design of our survey experiment means we are better placed to test the mechanisms through which information has an effect than the
small number of previous studies because the sample size in each country is around three times larger and we more extensively solicit people’s prior beliefs.

Seminal theories of preferences for redistribution imply that informing people they are relatively poorer than they thought would lead to greater concern about inequality and support for redistribution (e.g. Meltzer and Richard 1981; Benabou and Ok 2001, Piketty 1995). This is based on the assumption that people are averse to others in society having significantly different incomes to them and they are more concerned about the income gap between them and the richest in society as opposed to the income gap between them and the poorest in society (e.g. Fehr and Schmidt 1999; Alesina and Giuliano 2011). However there is little empirical support as only a small number of survey experiments have analyzed how information about inequality impacts people’s preferences for redistribution (Hauser and Norton 2017). There is only one survey experiment that directly tests the effect of informing people they are relatively poorer than they thought. Cruces, Perez-Truglia and Tetaz (2013) survey 1054 people in Buenos Aires and show informing people they are poorer than they thought led to greater support for redistribution, which is consistent with seminal theories. Yet there is also some evidence from related studies that would suggest informing people they are relatively poorer than they thought may reduce their desire for redistribution. For example, experimental research in the United States by Kuziemko et al. (2014) shows “last place aversion” can exist whereby relatively poor people often prefer when there are people who are poorer than them. Similarly, there are inconsistent findings from the few studies that examine the effect of informing people they are richer than they thought (Nair 2018; Karadja, Mollerstrom and Seim 2017).

We find respondents in the poorest two quintiles of the national income distribution who were told they are relatively poorer than they thought are less concerned about the gap between the rich and poor in their country and are not any more supportive of the government closing this gap compared to respondents in the control group. This result occurs in seven countries (India, Mexico, Morocco, Netherlands, Nigeria, South Africa and Spain) and there was no effect from this information in the remaining three countries (Australia, United Kingdom and the United States). The overall effect of the treatment was mainly driven by people who prefer low levels of inequality and by respondents in both the poorest quintile and the second poorest quintile in most countries. We also show there were no statistically significant effects from the treatment among respondents in the poorest two quintiles of the national income distribution who accurately estimated their position in the distribution. In addition, we conduct a series of robustness checks to illustrate the effect was not due to how many people lived in the household of respondents, the size of respondents’ misperceptions, the representativeness of the survey sample, differential attrition or a lack of attention paid during the survey (see Section 0.1 of the Online Appendix). Furthermore, we conduct an additional randomized survey experiment that replicates our original results and provides further insights as to the mechanism driving our results (see Section 0.2 of the Online Appendix).

We illustrate that the likely channel causing the effect is people using their own standard of living as a “benchmark” for what they consider acceptable for others by modifying Fehr
and Schmidt’s seminal model of other-regarding preferences and exploring heterogeneous treatment effects. This is consistent with the results to our study as follows. People had perceived themselves to have an “average” living standard compared to other people in their country prior to the treatment, even though they were actually relatively poor. Their previous assessment of their relative status implies they thought there was a similar share of people poorer than them and richer than them in their country (this is as a result of placing oneself as being around the middle of the national income distribution). Upon receiving the treatment this led people to realize two points. Firstly, there are fewer people in their country poorer than them than what they had thought. Secondly, what they had considered to be an average living standard (i.e. their own standard of living) is actually relatively poor. In other words, relatively poor people consume more than they thought. Both of these points would suggest the treatment provided to respondents would lead them to become less concerned about the living standard of poor people in their country. This notion of “benchmarking” is consistent with one of the key assumptions of most theories of preferences for redistribution, which is that relatively poor people are averse to others in society having significantly different levels of income to them. However, this study diverges from standard theory by showing relatively poor people are more concerned about the gap between their income and the poorest in society as opposed to the gap between their income and the richest in society.

This paper contributes to the existing understanding of how people’s perceptions of inequality shape their support for redistribution in at least two ways. Firstly, we identify a novel mechanism (that we refer to as “benchmarking”) through which people update their beliefs about inequality. This mechanism potentially helps to explain why poorer people are less supportive of redistribution than seminal theories of preferences for redistribution would suggest. Benchmarking means there are competing channels through which people think about redistribution. On the one hand, relatively poor people may be more supportive of redistribution if they believe they are set to benefit, but on the other hand they may be less supportive if they view the absolute living standard of relatively poor people as somewhat satisfactory and as such they are less likely to think redistribution to the poor is needed.

Secondly, we add to the growing evidence base that suggests seminal theories of preferences for redistribution should be modified to reflect the fact that most people do not have accurate information about the income distribution in their country (Gimpelson and Treisman 2018; Hauser and Norton 2017). We extend the stylized facts that poor people do not realize they are near the bottom of the national income distribution and their perceived, as opposed to actual, position in the distribution is more closely aligned with their preferences for redistribution from studies in North America and Europe to a diverse group of countries (Gimpelson and Treisman 2018; Hauser and Norton 2017). However the results of our experiment illustrate relatively poor people’s misperceptions of their position in the distribution do not appear to be lowering their concern about inequality. We provide evidence the opposite is true. Relatively poor people would be even less concerned about inequality if they knew their true position in the national income distribution. In addition,
we show that the elasticity of respondents’ preferences for redistribution to the treatment is substantially greater in middle-income countries than in high-income countries. This is a novel finding as it suggests the literature on preferences for redistribution may well be qualitatively different if more research were to be conducted in these settings.

This paper is structured as follows. Section I provides a theoretical framework of how informing people they are relatively poorer than they thought would impact their concern about inequality and explores how this framework relates to existing experimental studies on this topic. Section II outlines the methodology behind the randomized survey experiment and the econometric analysis we conduct. Section III illustrates that the descriptive trends from our survey data are consistent with previous research. Sections IV and V present the results of the randomized survey experiment and discuss how the findings relate to existing theories of preferences for redistribution.

I. Theory and Related Literature

A. Assumptions underpinning theories of preferences for redistribution

Seminal theories of preferences for redistribution tend to be based on the following three assumptions (Alesina and Giuliano 2011). Firstly, most people are averse to large income differences in their country and this is particularly the case for relatively poor people. Secondly, people who are more concerned about inequality tend to be more supportive of redistribution. Thirdly, poorer people should be more supportive of redistribution than richer people as they benefit directly.

To illustrate formally these assumptions about people’s preferences for the distribution of income in their country, we start with a seminal model of other-regarding preferences (Fehr and Schmidt 1999)\(^1\). For simplicity we follow Fehr and Schmidt (1999) and assume that an individual’s utility function \((U_i(x))\) is linear in inequality aversion and in their own consumption, concave and that disutility from inequality is self-centered (i.e. people care about how their consumption relates to other people’s consumption but do not care about inequality between other people’s consumption per se). The generalized version of this model for a set of \(n\) people can be written as follows for individual \(i\):

\[
U_i(x) = x_i - \beta_i \frac{1}{n-1} \left( \sum_{j \neq i} \max[x_i - x_j, 0] \right) - \gamma_i \frac{1}{n-1} \left( \sum_{k \neq i} \max[x_k - x_i, 0] \right)
\]

This model captures clearly how an individual’s utility depends on their own consumption \((x_i)\) as well as the direction and size of the weighting they place on their consumption relative to people poorer \((x_j)\) than them \((\beta)\) and richer \((x_k)\) than them \((\gamma)\). Importantly, in this model the weighting people place on their consumption relative to others (i.e. \(\gamma\) and \(\beta\)) is independent of the size of differences in consumption. For example, in a simple

\(^1\)While their model refers to consumption, we follow Kuziemko et al. (2015) and focus on income in this paper.
three-person version of this model\(^2\) it is possible that individual \(i\) may place a much larger weight on their consumption relative to the rich person \((x^*_k - x_i)\) than the poor person places on this difference in consumption \((x^*_k - x^*_j)\). As such even though the consumption gap is larger for the poor person their level of disutility from the consumption difference between them and the rich person may be smaller than the disutility that individual \(i\) experiences (this would occur if \(\frac{x^*_k - x^*_j}{x^*_k - x_i} < \frac{\gamma_k}{\gamma_j}\)).

As mentioned above, Fehr and Schmidt (1999) along with other seminal theories of preferences for redistribution assume people are averse to others having significantly different consumption to them \((\gamma > 0, \beta > 0)\) (see Alesina and Giuliano 2011). Therefore the presence of inequality lowers people’s utility even though it may not have a direct effect on their own consumption. In addition, they assume that on average people’s disutility from differences in consumption is larger for the gap between them and those richer than them as opposed to the gap between them and those poorer than them \((|\gamma| > |\beta|\)). Collectively, these assumptions imply \(\gamma > \beta > 0\). Therefore, in a country with a set amount of inequality on average individuals close to the top of the distribution have higher utility (beyond just having a higher level of consumption) than those who are closer to the bottom of the distribution. As a result, for a given weighting on income differences the poorer an individual is the more likely they are to experience disutility from the gap between the rich and poor in their country.

Seminal theories also assume that people’s concern about inequality tends to be related to their support for redistribution (e.g. Benabou and Ok 2001). As such individuals that place a greater weighting on their consumption relative to others (i.e. they experience greater disutility from inequality) are more likely to prefer the government intervenes to reduce income differences in society. However if people have a high level of concern about inequality this may not always mean they have a high level of support for redistribution. For example, if an individual lacks trust in the government then they may be concerned about inequality but not support redistribution as they believe the government will not address the problem. Therefore changes in other-regarding preferences could be considered a necessary but not sufficient condition for preferences for redistribution to change.

Another key assumption of most seminal theories of preferences for redistribution is that poorer people should be the most supportive of redistribution as they benefit directly. For example, the Meltzer-Richard hypothesis proposes people below the median income in the national income distribution should support redistribution and the richest in society should not (Meltzer and Richard 1981). This is based on whether the individual is potentially set to directly benefit or lose from redistribution. In terms of the utility function above, individual \(i\) considers whether their consumption level \((x_i)\) will be higher or lower under certain levels of redistribution and this is what determines whether they are supportive.

\(^2\)Where there is one person poorer than individual \(i\) and one person richer than individual \(i\).
B. How correcting misperceptions may change preferences

To illustrate how correcting misperceptions may change preferences we modify Fehr and Schmidt’s model to reflect recent research indicating that people misperceive their position in the distribution and their perceptions are more closely correlated with their preferences than what is actually the case (Gimpelson and Treisman 2018; Hauser and Norton 2017; Niehues 2014). Specifically, we show an individual’s utility is dependent on how they perceive the consumption of the other people, as opposed to the actual level of consumption of other people. The generalized model becomes:

\[
U_i(x) = x_i - \beta_i \frac{1}{n-1} \left( \sum_{j \neq i} \max[x_i - x_j, 0] \right) - \gamma_i \frac{1}{n-1} \left( \sum_{k \neq i} \max[x_k - x_i, 0] \right)
\]

whereby; \(x_j^P = \) perceived consumption of people poorer than \(x_i\) and \(x_k^P = \) perceived consumption of people richer than \(x_i\).

This revised model provides a framework to demonstrate how information about an individual’s position in the national income distribution that corrects their existing misperceptions is likely to impact their preferences. We assume that our experiment changes the information set respondents have available to them from \(I^0\) to \(I^1\). It is important to note that we are exclusively referring to correcting people’s misperceptions of their relative consumption, as it is reasonable to assume people have complete information about their own consumption. While Fehr and Schmidt’s model does not explicitly predict how preferences change when individuals are provided with information, we follow Card et al. (2012) who modify this type of utility function to illustrate how people respond to information about their relative position in a distribution. If the assumptions underlying seminal theories of preferences for redistribution are valid, this would imply the following hypotheses:

**Hypothesis 1:** Informing people they are relatively poorer than they thought will increase their concern about the gap between the rich and poor in their country.

This hypothesis is expected to hold as the information will lead people to realize the gap between their income and people richer than them is larger than they thought and seminal theory assumes people are averse to inequality and are primarily concerned about the gap between their income and people richer than them (i.e. \(\gamma > \beta > 0\)). This can be written formally as:

\[
\text{if } \frac{\sum_{k \neq i}(x_k - x_i)}{\sum_{j \neq i}(x_i - x_j)} > \frac{\sum_{k \neq i}(x_k^P - x_i)}{\sum_{j \neq i}(x_i - x_j^P)} \text{ then } [U_i(x)|I^1] < [U_i(x)|I^0]
\]

**Hypothesis 2:** Informing people they are relatively poorer than they thought
will increase their support for the government to reduce the gap between the rich and poor.

This hypothesis is expected to hold for two reasons. Firstly, this information will make people more concerned about inequality in their country (see Hypothesis 1) and seminal theories typically assume this will lead to a greater desire for redistribution. Secondly, this information will lead poorer people to realise they are more likely to be a direct beneficiary of redistribution from rich to poor. As such they should have a higher level of consumption \( x_i \) if there is greater redistribution and this will raise their utility.

If we find evidence contrary to the first hypothesis, then this would suggest that one of the key assumptions underpinning Fehr and Schmidt’s model and most seminal theories of preferences for redistribution lacks empirical support. People may not be averse to others consuming significantly differently to them \( \gamma \leq 0, \beta \leq 0 \) or they may experience greater disutility from the gap between their consumption and those poorer than them as opposed to the gap between their consumption and those richer than them \( |\gamma| < |\beta| \). If either of these are the case then informing people they are relatively poor will actually lower their concern about inequality because they are being told the gap between their income and the income of those below them is smaller than what they had thought \( \sum_{j \neq i}(x_i - x_j) < \sum_{j \neq i}(x_i - x^{P_j}) \).

It is ambiguous what the effect of informing people they are poorer than they thought will be in terms of the second hypothesis if the first hypothesis is not confirmed because this means there are competing channels through which people think about redistribution. On the one hand, poorer people may be more supportive if they are set to benefit from redistribution, but on the other hand they may be less supportive if they are less concerned about the degree of inequality in their country. The net result will depend on the size of the weighting that people place on their consumption relative to others.

\[ C. \quad \text{Related literature} \]

Only a relatively recent and small literature of randomized survey experiments exists that analyze how people’s preferences for redistribution are impacted by information (Hauser and Norton 2017). Influential studies by Kuziemko et al. (2015) and Alesina, Stantcheva and Teso (2018) show that preferences for redistribution can be elastic to information about inequality, however neither test the hypotheses above. For example, Kuziemko et al. (2015) conduct a series of randomized survey experiments in the United States and find that only information about estate taxes was able to increase support for redistribution. The only cross-country survey experiment that relates to the research question in this paper provides a treatment with multiple pieces of information about inequality to respondents, including their position in the national income distribution (Bublitz 2016). This treatment reduced support for redistribution among people who were richer than they thought in Germany and Russia but had no effect in the remaining four countries (France, Spain, Brazil and the United States). It is challenging to identify the mechanisms that are causing this outcome as respondents were provided with various pieces of information about inequality in their
country as well as information about their position in the distribution. There are four key studies in the literature (all of which are only based in a single country) that relate closely to the hypotheses above and their findings have direct implications about the shape of people’s utility in our model. There is only one survey experiment that directly examines the impact of informing people they are poorer than they thought on their support for redistribution. Cruces, Perez-Truglia and Tetaz (2013) present a theoretical model based on the idea that misperceptions of inequality are due to people extrapolating information from endogenous reference groups. They test this by conducting a household survey experiment of 1054 respondents in Buenos Aires (the capital of Argentina) and show that information about people’s position in the national income distribution boosts support for redistribution among people who were relatively poorer than they thought. This result (i.e. $\gamma > \beta > 0$) is consistent with the hypotheses in our paper. A related study by Kuziemko et al. (2014) provides evidence from laboratory experiments and surveys in the United States that “last place aversion” can exist whereby people near the very bottom of the distribution are the least supportive of redistribution, particularly in the form of increases in the minimum wage. It is argued that this is because poor people prefer a gap between their income and that of people relatively poorer than them. This finding (i.e. $\beta < 0$) is inconsistent with the hypotheses above.

There are two similar survey experiments that examine the effect of informing people that they are relatively richer than they thought. The first, by Karadja, Mollerstrom and Seim (2017), draws on a postal survey experiment of 1001 respondents in Sweden and shows that informing people they are relatively richer than they thought lowers support for redistribution. This result is compatible with the hypotheses in our paper (i.e. $\gamma > \beta > 0$). The second, by Nair (2018), involves an online survey experiment of 1559 respondents in the United States and shows that when people were told they were relatively richer than they thought in terms of global income distribution, they became more supportive of international redistribution. Nair argues that this finding is because people are averse to a large gap in incomes between them and the poorest people in the world. This finding (i.e. $\beta > \gamma > 0$) is incompatible with the hypotheses above.

II. Methodology

This study helps fill the gap in the literature about how relatively poor people’s misperceptions of their position in the national income distribution impacts their support for redistribution by testing the hypotheses above.

A. Sample selection and sample size

We conducted a randomized survey experiment with over 30,000 respondents in 10 countries (Australia, India, Mexico, Morocco, Netherlands, Nigeria, South Africa, Spain, the

---

3Almost all respondents to this study either underestimated or accurately estimated their position in the income distribution. As such the sample size was too small (i.e. inadequate statistical power) for the authors to examine the hypotheses above.
United Kingdom and the United States) during the last three months of 2017. These countries make up around 30 per cent of the global population and represent about 40 per cent of world GDP. The diverse set of countries was selected so as to provide confidence in the external validity of the results of the survey experiment and to ensure at least one country was included from Asia, Sub-Saharan Africa, Latin America, Middle East and North Africa, Europe, North America and Oceania. There is significant variation between the countries in this study in terms of the level of income, inequality, government intervention in the economy, state fragility and the degree of individualism (see Table 1).

Data was collected of a representative sample of the population with internet access in each country using internationally respected online surveys firms YouGov, IPSOS and RIWI, which is the same approach as was used by Alesina, Stantcheva and Teso (2018). This resulted in a sample of respondents where younger people and men were overrepresented compared to a perfectly nationally representative sample, especially in developing countries (see Table OA1 in the Online Appendix). Throughout the body of the paper we present the sample average treatment effect, and to address concerns about the representativeness of the sample we present the treatment effects weighted by the age and gender of the national population as a robustness check in the Online Appendix (see Section 0.1 in the Online Appendix). In general, the effects are qualitatively similar.

In every country, the treatment and control groups had at least 800 respondents and on average there were around 1500 respondents in each group. This is a similar sample size in each country to what was used in Kuziemko et al. (2015) and Alesina, Stantcheva and Teso (2018). Previous studies that just provided information about a respondent’s position in the distribution only had around 500 respondents in the treatment group (Cruces, Perez-Truglia and Tetaz 2013; Karadja, Mollerstrom and Seim 2017). As such we have substantially more statistical power to detect heterogeneous effects, such as differences in the effect of information between people based upon their pre-existing preference for inequality.

**B. Survey design**

The survey consisted of two sections; the first collected people’s existing perceptions of inequality and demographic characteristics, while the second included questions about people’s concerns about inequality and desire for government action (see Section 0.3 in the Online Appendix for a full list of questions). The demographic characteristics section included questions about respondents’ voting preferences, their total household income and the number of people in each respondent’s household. The latter two questions were used to estimate the position of each respondent in the national income distribution. As is the case in all studies that rely on reported income there is a risk respondents do not provide correct information about their household’s actual income (World Bank 2014). To minimize the likelihood of this occurring we follow the example of a seminal randomized
survey experiment on perceptions of inequality by Alesina, Stantcheva and Teso (2018). Specifically, we first asked respondents how many people lived in their household. We then required respondents to select their actual household income from a list of five options that contained bands of income levels (e.g. less than $10,000, $10,000-$20,000, etc). We designed the survey so that these options would adjust based on the reported number of people living in each respondent’s household, so that the five options corresponded with the five quintiles of the national income distribution. This type of closed question minimizes the likelihood of measurement error as respondents were not free to enter any number and they could review the complete set of options prior to selecting an answer.

To measure respondents’ perceptions of the level of national inequality, previous studies have used a range of techniques including stylized distributions (ISSP 2009) or asking respondents to estimate quintile shares (Norton et al. 2011). We follow the rationale behind existing approaches, however we minimize measurement error by gathering people’s perceptions in an ordinal sense (Kuhn 2015). Respondents were asked to select one of six options that could represent the distribution of income in their country, ranging from perfectly equal to extremely unequal (see Figure 2a). They were then asked to select the level of national inequality they would prefer to exist using the same set of options (see Figure 2b). The questions were identical for respondents in each country. As these questions only gather people’s perceptions in a qualitative sense, we are unable to determine the extent to which people accurately estimated the level of inequality. We compare respondents’ answers to the question about their perceived level of inequality and preferred level of inequality to determine if they would prefer lower levels of inequality than what they believe currently exists.

[Insert Figure 2]

Respondents were also asked about which quintile they perceived their household to fall into in the national income distribution (see Figure 3). This approach of using a limited number of options for respondents to select from is similar to other studies4 (e.g. Cruces, Perez-Truglia and Tetaz 2013 and Karadjia, Mollerstrom and Seim 2017) as asking respondents their exact percentile or rank in the distribution is likely to have a large margin of error. As we are using the fairly coarse measure of quintiles our estimates are likely to dramatically underestimate the extent to which people misperceive their position in the distribution. Therefore the results of our survey should be considered a lower bound estimate of the effect of correcting people’s misperceptions of their position in the distribution.

[Insert Figure 3]

To determine people’s misperception of their position in the income distribution, we compare respondents’ answers to the question about their perceived quintile in the national

4The main difference is that we use quintiles in this study (as opposed to deciles) to make it easier for people to understand even if they lack basic numeracy.
distribution to their actual quintile in the national income distribution (based on their self-reported household income). We categorize people based on if they accurately, under (relatively richer than they thought) or overestimated (relatively poorer than they thought) their position. Importantly, our treatment is based on self-reported household income so that way we can be confident the only new component of the information we provide to respondents is their relative position. If we were to rely on another source of information for people’s income as some other studies have done (e.g. Karadja, Mollerstrom and Seim 2017), we would not be able to be confident the treatment effect is purely due to people being informed about their relative position. In these other studies the treatment effect could potentially be driven by the fact the information provided from another source about people’s own income is higher or lower than what they believe to be the case.

The second part of the survey included questions about respondents’ concern about inequality and their support for redistribution (see Table 2). These questions were sourced from previous studies, specifically the International Social Survey Programme (ISSP) (2009) and Alesina, Stantcheva and Teso (2018). Importantly, the question we ask about support for redistribution is quite explicit that it is referring to redistribution from rich to poor, which means it is very difficult to argue that respondents did not realise that the poor are meant to benefit more than the rich from redistribution (Holland 2018). We also ensured the questions we asked about people’s concern about inequality and support for redistribution were clearly linked. This allows us to easily make close comparisons between how people respond to the two questions (i.e. it is reasonable for us to compare the share of people who agree with both statements in each country), as previous studies have done (e.g. Niehues 2014).

Prior to answering the second section of the survey, respondents were randomly allocated to either receive information about which quintile in the national income distribution they belonged to (see an example in Figure 4) or no information (the control group). The treatment was designed in a way to only provide respondents with information about their relative position in the income distribution and not provide direct information about the income distribution in general. This was to ensure we could speak directly to the hypotheses discussed in Section I and avoid complicating the interpretation of the treatment effect. Randomization ensured the effect of information could be determined by comparing average differences in answers to questions between the treatment and control groups. There were few statistically significant differences between treatment and control groups across demographic characteristics and existing perceptions of inequality in each country (see Table OA2 in the Online Appendix). Data about the income distribution in each country was sourced from the World Bank (World Bank 2017A; World Bank 2017B) for the middle-income countries and the OECD for high-income countries (OECD 2017).

We designed our study to minimize the risk the findings would be impacted by measurement issues that can arise in survey experiments. Firstly, there is a risk a “placebo effect”
or “priming” may occur whereby simply mentioning inequality could trigger a response irrespective of the exact content of the treatment (Nair 2018; McCall 2017). We address this concern by asking all respondents prior to the treatment about their views on the level of national inequality and their perceived position in the national income distribution. As such, all respondents were already thinking about inequality (i.e. both treatment and control groups were “primed”) prior to the treatment being provided, which dramatically reduces the likelihood there is a placebo effect from the treatment itself.

Secondly, a potential risk in a survey experiment is that results are skewed due to “experimenter demand effects” or “social desirability bias” (Kuziemko et al. 2015), whereby respondents provide either answers they think the experimenter would want to hear or answers they perceive as more socially acceptable. In our study this could look like respondents pretending to be more altruistic (measured as being concerned about inequality in their country) than they actually are. Existing studies on this topic (e.g. Kuziemko et al. 2015, Alesina, Stantcheva and Teso 2018) have illustrated that these issues are not very prevalent in randomized survey experiments about preferences for redistribution by taking steps such as conducting follow up surveys to a small subset of respondents a week after the original survey. They have consistently found that experimenter demand effects are not present. In our survey we also took a number of steps to minimize the likelihood “experimenter demand effects” or “social desirability bias” is impacting our results as all respondents remained anonymous and the surveys were conducted online so there was no direct human interaction associated with completing the survey. Furthermore, there was no incentive structure that could lead respondents to believe they could answer the survey in a way to increase their likelihood of getting to participate (or avoid participating) in a future survey. This is an advantage of our study over previous research that relies on platforms like Mechanical Turk, whereby respondents know they may be reviewed based on the answers they provide to the survey (e.g. Kuziemko et al. 2015).

C. Empirical model

We capture the effect of information by comparing average responses to the questions in Table 2 between the treatment group and the control group, using an Ordinary Least Squares (OLS) regression with a binary dependent variable (i.e. a linear probability model). This involves creating a dummy variable for each question \(Y_j\) in Table 3 which takes on the value 1 if the respondent strongly agrees or agrees with the statement in question \(j\) and the value 0 if the respondent does not select one of these options. We also create a dummy variable for the treatment group \(T\), which takes on the value 1 if the respondent belongs to the treatment group and the value 0 if the respondent belongs to the control group. We pre-registered the design of this study with the American Economic Association Randomized Control Trial registry (ID number AEARCTR-0002534 and AEARCTR-0002614) (Hoy and Mager 2017).

In the body of the paper, we focus the analysis on the effect of information in each country individually because the information provided is tailored to the income distribution of each country, the questions relate to redistribution by the national government, and the political
economy within each country differs. However for completeness we also present the main results of the survey experiment using pooled OLS regressions with country fixed effects across all countries and we also run pooled regressions for middle-income and high-income countries separately.

Our main regression model can be written formally as follows:

\[ Y_j = \beta_0 + \beta_1 T + X\gamma + \varepsilon, \]

Where \( \beta_1 \) captures the average difference in the share of respondents in the treatment and control groups that agreed with the statement in question \( j \) (i.e. the treatment effect). \( X \) is a vector of variables that controls for potential imbalance in background characteristics between the treatment and control groups, \( \beta_0 \) is the intercept term and \( \varepsilon \) is the model error term.

We analyze the heterogeneous treatment effects from information in regards to people’s actual position in the distribution, perceived level of inequality and preferred level of national inequality. In addition, we conduct a series of robustness checks including testing the effect of information using an ordered logit model. To do this we follow a similar approach to the main type of analysis whereby we capture the difference in responses between treatment and control groups using the co-efficient of a dummy variable for the treatment group (i.e. \( T \)).

### III. Data

This section first examines whether the descriptive findings from our survey data are consistent with the assumptions underlying seminal theory and then we examine the extent that misperceptions about people’s position in the income distribution are present.

#### A. Empirical support for assumptions underlying theories of preferences for redistribution

This subsection illustrates our survey data provides empirical support for most of the assumptions of seminal theories of preferences for redistribution except it shows that there is surprisingly little difference between relatively poor and rich people’s desire for lower inequality, concern about inequality and support for redistribution.

**People are averse to inequality. —** Consistent with seminal theories, we find compelling evidence across countries that people are averse to inequality. Figure 5 shows the share of respondents in each country that perceive high levels of inequality exist and the share of respondents that prefer high levels of inequality. Between 52 to 74 percent of respondents perceive high levels of inequality (the highest being in the United Kingdom and lowest in the Netherlands) and between 10 to 29 percent of respondents prefer high levels of inequality (the highest being in Nigeria and the lowest in the United Kingdom). However contrary to the assumptions of seminal theories, relatively poor people tend to have similar
preferences for inequality to be lower than what they perceive it to be as relatively rich people (see Figure OA1 in the Online Appendix). This pattern whereby poorer people do not seem to have substantially different preferences in regards to inequality than richer people is consistent with what has been observed in other studies (Kuziemko et al. 2014; Roemer 1998; Holland 2018) and is shown in Figure 1. We find there are some countries where richer people tend to be less likely to desire lower levels of inequality (Spain, Mexico and the Netherlands), however there are others where the opposite is the case (India and South Africa).

[Insert Figure 5]

**Being concerned about inequality is related to supporting redistribution.** — Across countries there is a clear pattern whereby being concerned about inequality tends to be related to supporting redistribution (see Figure OA2 in the Online Appendix). Between 58 per cent (in the Netherlands) to 79 per cent (in Nigeria) of respondents agreed that the gap between the rich and poor people is too large in their country and that the government is responsible for closing this gap. An additional 11 per cent (in Spain) to 23 per cent (in Morocco) said they agreed the gap between the rich and poor is too large, but did not agree the government was responsible for closing this gap. Only a relatively small share of the population in each country (between 3 to 8 per cent) stated they support redistribution but are not concerned about inequality. These descriptive statistics are in line with the assumptions of seminal theories whereby being concerned about inequality would appear to be a necessary but not sufficient condition for supporting redistribution.

We find very little support for a key assumption in seminal theories, which is poor people should be considerably more concerned about inequality and supportive of redistribution than rich people (see Figures OA3 and OA4 in the Online Appendix). There are relatively small differences in the shares of relatively rich and relatively poor people who agree the gap between the rich and poor is too large and that the government is responsible for closing this gap. This builds on the finding we present above whereby relatively rich and poor people tend to have similar preferences for lower inequality across countries.

**B. Misperceptions of people’s position in the distribution**

This subsection illustrates that large misperceptions exist about the position of respondents in the distribution and these perceptions are correlated with people’s policy preferences.

**Relatively poor people’s misperception of their position in the distribution.** — The vast majority of respondents from the poorest two quintiles of the national income distribution in each country were unable to accurately estimate which quintile in the distribution their household belonged to (this is calculated by drawing on responses to the question shown in Figure 3). Between 37 per cent (in the United Kingdom) to 63 per
cent (in India) of respondents from the poorest two quintiles of the national income distribution perceived their household to be in the middle quintile of the national income distribution (see Figure 6). We call this common misperception a “median bias” and it has also been observed in a number of studies about perceptions of inequality in high-income countries (e.g. Gimpelson and Treisman 2018). The presence of a median bias means that people who are actually poor tend to overestimate their position in the national income distribution. Between 67 per cent (in the United Kingdom) to 94 per cent (in Nigeria) of respondents in the poorest two quintiles overestimated their position (see Figure OA5 in the Online Appendix). Only between 5 per cent (in Nigeria) to 29 per cent of respondents (in the United Kingdom) accurately estimated their position\textsuperscript{5}. Interestingly, respondents in high-income countries were over 50 per cent more likely to accurately estimate their quintile in the national income distribution than respondents in middle-income countries (21 per cent answered accurately compared to 13 per cent).

[Insert Figure 6]

**Relationship between perceived position in the national income distribution and preferred level of national inequality.** — The majority of respondents in the poorest two quintiles in all countries (except India) prefer lower levels of inequality than what they perceive to exist, however this varies considerably depending on their perceived position in the national income distribution. Across all countries relatively poor respondents (i.e. those in the poorest two quintiles) who perceived themselves to be in the poorest two quintiles of the national income distribution preferred lower levels of inequality than relatively poor people who perceived themselves to be in the middle or richest two quintiles (see Figure 7). The difference between the share of respondents in these two groups is statistically significant at a p-value of 0.05 in all countries. This finding is consistent with recent evidence in high-income countries that suggests people’s perception of their position in the distribution is a better predictor of their redistributive preferences than what is actually the case (Gimpelson and Treisman 2018; Niehues 2014; Hauser and Norton 2017).

[Insert Figure 7]

**IV. Results**

In the previous section we showed that relatively poor people were not substantially more concerned about inequality and supportive of redistribution than relatively rich people and presented evidence that this may be because people misperceive their relative position in the distribution. In this section, we test whether this is the case and our results draw into question an assumption underlying seminal theories of redistribution.

\textsuperscript{5}Only a trivial share of respondents in the second poorest quintile underestimated which quintile in the national income distribution they belonged to. It is not possible for respondents in the poorest quintile to underestimate the quintile they belong to.
A. Effect of the treatment on relatively poor people who overestimated their position in the distribution

Country-level effects of the treatment. — Informing respondents in the poorest two quintiles of the national income distribution they are relatively poorer than they thought led them to be less likely to agree the gap between the rich and poor is too large in their country. This treatment effect is statistically significant in seven of the ten countries in our study (India, Mexico, Morocco, Netherlands, Nigeria, South Africa and Spain) and there is no effect in the remaining three countries (Australia, United Kingdom and the United States) (see Figure 8 and Table 3). Among the seven countries where there is a statistically significant effect, the difference between treatment and control groups is between negative 7.9 and negative 3.7 percentage points. For example, in the case of Spain 78.5 per cent of respondents in the control group (who overestimated their position and are actually in the poorest two quintiles) agree the gap between rich and poor is too large, whereas the share of respondents that agree in the treatment group (who overestimated their position and are actually in the poorest two quintiles) is 70.6 per cent. In each of the 10 countries, this information does not lead to a statistically significant impact on people’s views about whether the government is responsible for closing the gap between the rich and the poor.

To illustrate the magnitude of the treatment effect on people’s concern about inequality, we re-run the regression analysis above with an inverted outcome variable (i.e. the share of respondents that do not agree the gap between the rich and poor is too large in their country). We do this as concern about inequality is already very high in the control group and this somewhat masks the impact of the treatment. We show in Figure 9 that the share of respondents that do not agree the gap between the rich and poor is too large is up to twice as high in the treatment group (in the case of Nigeria). On average, in the countries where there is a statistically significant effect, the treatment increases the share of respondents who do not agree the gap between the rich and poor is too large by almost 40 per cent.

Pooled effects of the treatment. — To examine the effect of the information across all countries, we also conducted pooled OLS regressions with country fixed effects. This allows us to have greater statistical power to detect the impact of the information when it exists. We show in Table 4 below the results of this analysis. Consistent with the country-level results the treatment lowered concern about inequality across all countries, but primarily in middle-income countries. Interestingly, we also find a small positive effect from the treatment on support for redistribution across all middle-income countries.
B. **Heterogeneous treatment effects**

**Main results disaggregated by respondents’ prior preferences for inequality.** —
The effect of information on people’s concern about the gap between the rich and poor is largely driven by respondents who stated prior to the treatment that they prefer low levels of national inequality (see Table OA3 in the Online Appendix). In six of the seven countries where there is a significant effect in Table 3, the effect is driven by respondents who stated prior to the treatment that they prefer low levels of inequality (in India, Mexico, Netherlands, Nigeria, South Africa and Spain). Among these six countries the difference between the treatment and control groups was between negative 8.5 and negative 5.9 percentage points. The exception is in Morocco where the overall effect of the treatment is driven primarily by people who prefer high levels of inequality; among this group of respondents the difference between treatment and control groups was negative 11.7 percentage points. There are no statistically significant treatment effects in terms of respondents’ views about the responsibility of the government in closing the gap between rich and poor among people who stated prior to the treatment they prefer high or low levels of national inequality.

**Main results disaggregated by respondents’ prior perceptions of inequality.** —
The effect of the treatment did not vary systematically across countries by respondents’ prior perceptions of the level of inequality in their country (see Table OA4 in the Online Appendix). There are four countries (India, Nigeria, the Netherlands and South Africa) where the effect is significant for respondents who perceived low levels of inequality and three countries (Spain, Mexico and Nigeria) where the effect is significant for respondents who perceived high inequality. There are no statistically significant treatment effects in terms of respondents’ views about the responsibility of the government in closing the gap between rich and poor among people who stated prior to the treatment they perceive high or low levels of national inequality.

**Main results disaggregated by respondents’ actual quintile in the distribution.** —
The treatment impacted respondents in both the poorest and second poorest quintile, however the results are often not statistically significant (see Table OA5 in the Online Appendix). The treatment effect is only statistically significant in five of the countries when restricting the sample to respondents in the poorest or second poorest quintile. The point estimate tends to be larger in the case of respondents in the second poorest quintile. As is the case above, there is little effect from information on people’s views about the role of the government in closing the gap between the rich and poor among respondents in both the poorest and second poorest quintiles. Nigeria is the only country where there is an effect, in which case there are opposite effects between people who are in the poorest and second poorest quintiles.
V. Discussion

This study shows that informing people in the poorest two quintiles of the national income distribution that they are relatively poorer than they thought leads them to be less likely to agree that the gap between the rich and poor in their country is too large, and does not have a statistically significant effect on their desire for the government to reduce this gap. These results are primarily driven by people who prefer low levels of inequality and are from both the poorest and second poorest quintile in the national income distribution.

A. Channel through which information is having an effect

Our findings are clearly counter to the hypothesis that informing people they are relatively poorer than they thought will increase their concern about the gap between the rich and poor (Hypothesis 1). We also do not find statistically significant effects in line with the hypothesis that the treatment will increase people’s support for the government to reduce the gap between the rich and poor (Hypothesis 2).

To relate these findings to our model in Section I, recall that the utility function captures clearly how an individual’s utility ($U_i(x)$) depends on their own consumption ($x_i$) as well as the direction and size of the weighting they place on their consumption relative to people poorer than them ($\beta$) and richer than them ($\gamma$). As mentioned above, seminal theories of preferences for redistribution assume people are averse to others having significantly different consumption to them and that on average people’s disutility from differences in consumption is larger for the gap between them and those richer than them as opposed to the gap between them and those poorer than them (Alesina and Giuliano 2011). Collectively, these assumptions imply $\gamma > \beta > 0$. Our results only support the assumption that relatively poor people are averse to large differences in incomes across society. This can be seen in the descriptive statistics we show in Section III and by the fact that the treatment effect is primarily driven by relatively poor people who had expressed a prior preference for low levels of inequality (i.e. where $\gamma > 0$, $\beta > 0$) in all countries except for Morocco.

Our findings do not support the assumption that on average people’s disutility from differences in consumption is larger for the gap between them and those richer than them as opposed to the gap between them and those poorer than them. When people are told they are relatively poorer than they thought, this implies the gap between them and people poorer than them is smaller than they thought and the gap between them and people richer than them is larger than they thought. They respond by being less concerned about the gap between the rich and poor in their country, even though they prefer low levels of inequality. This response is only consistent with poorer people being more concerned about the gap between their income and those poorer than them compared to the gap between their income and those richer than them (i.e. $\beta > \gamma > 0$). If this was not the case, the treatment effect would be in the opposite direction.

We refer to this updating of beliefs as “benchmarking”, whereby people use their own standard of living as a reference point for what they consider acceptable for others. The following explains how “benchmarking” is consistent with the results to our study. People
had perceived themselves to have an “average” living standard compared to other people in their country prior to the treatment, even though they are actually relatively poor. Their previous assessment of their relative status implies they thought there was a similar share of people poorer than them and richer than them in their country (this is as a result of selecting oneself as being around the middle of the national income distribution). Upon receiving the treatment this led people to realize two points. Firstly, there are fewer people in their country poorer than them than what they had thought. Secondly, what they had considered to be an average living standard (i.e. their own standard of living) is actually relatively poor. In other words, relatively poor people consume more than they thought. Both of these points would suggest the treatment provided to respondents would lead them to become less concerned about the living standard of poor people in their country. Consequently, this would result in them becoming less likely to agree the gap between the rich and poor in their country is too large, given their utility is weighted as we show it is above (i.e. $\beta > \gamma > 0$).

To illustrate this concept of benchmarking, consider a respondent in the second poorest quintile in India in the treatment group who prior to the treatment thought they were in the middle quintile. Upon receiving the treatment this would lead them to realize two pieces of information. Firstly, there are substantially fewer people in India poorer than them than what they had thought (i.e. instead of there being over half a billion people poorer than them they find out there are around two hundred and fifty million). Secondly, what they thought was an average standard of living (i.e. their living standard) is actually relatively poor. This means that relatively poor people in India consume more than what they had thought to be the case. As such there are fewer people poorer than them than what they thought and the absolute living standard of the relatively poor is higher than they thought. Therefore the respondent would become less concerned about the living standard of poor people in India as a result of the treatment.

### B. Implications for theories of preferences for redistribution

The results of our study have significant ramifications about the validity of the assumptions underlying seminal theories of preferences for redistribution. As discussed above, it is generally assumed that people who are more concerned about inequality tend to be more supportive of redistribution and poorer people should be more supportive of redistribution than richer people as they benefit directly. Our results suggest that these two assumptions reflect competing channels through which relatively poor people think about redistribution. This can be seen as follows. We find that informing people they are relatively poorer than they thought lowers their concern about inequality, which seminal theories would suggest should also lower their support for redistribution. However, seminal theories would also suggest that informing people they are relatively poorer than they thought should increase their support for redistribution as they are set to benefit directly. Given these competing channels it is unsurprising that we fail to detect a statistically significant effect on support for redistribution in any country.

The presence of competing channels through which relatively poor people think through
preferences for redistribution implies that seminal theories need to be revised. For example, the Meltzer-Richard hypothesis (1981), put simply, proposes that people below the median income in the distribution should be the most supportive of redistribution. This is based on whether an individual is potentially set to directly benefit or lose from redistribution. However, benchmarking would imply there is also an effect in the opposite direction. Even though relatively poor people may be likely to benefit from redistribution they are also less concerned about the absolute living standard of people who are relatively poor and as a result are less likely to think redistribution to the poor is needed.

This is supported by an additional survey experiment that we conduct in Australia (details in Section 0.2 in the Online Appendix) that shows how there is considerable heterogeneity between respondents within countries based on their satisfaction with the status quo. Relatively poor people who were satisfied with their current income responded to the treatment by becoming less supportive of redistribution, while the opposite is the case for respondents who were unsatisfied. This is consistent with the idea that people “benchmark” their living standard relative to others and poor people who are more satisfied with their income are less concerned about the absolute living standard of other relatively poor people and as a result are less likely to think redistribution is needed.

The net effect on preferences for redistribution of informing people they are relatively poorer than they thought will ultimately depend on the size of the weighting they place on their consumption relative to others. Our results suggest that on average people place a non-zero weighting on the consumption of others relative to their own income (i.e. $\beta > \gamma > 0$), however they are still primarily concerned about their own consumption ($1 >> \beta, 1 >> \gamma$). This can be seen from the fact that there is a significant negative treatment effect on concern about inequality, but often a positive insignificant effect on support for redistribution in most countries. This nuanced relationship is even clearer when examining the results of the pooled regressions with country fixed effects across middle-income countries as there is a statistically significant decrease in concern about inequality and statistically significant increase in support for redistribution. This can be reconciled by the fact that on average people are experiencing less disutility from inequality (the effect on concern about inequality), but on balance they are still slightly more supportive of redistribution as they are more likely to benefit directly.

The size of the weighting people place on other people’s consumption is likely to vary considerably across respondents and between countries. It is quite striking that the three countries that rank the highest in terms of having an individualist culture in Table 1 (Australia, the United Kingdom and the United States) (Hofstede Insights 2020) do not have statistically significant effects from the treatment on people’s concern about inequality. This is consistent with the idea that “benchmarking” is likely to be less common in countries with more individualistic cultures. In these countries, people would place smaller weights on their consumption relative to others. In addition, we find these three countries have the highest share of relatively poor people who accurately estimate their position in the distribution in the first place (see Figure OA5 in the Online Appendix). As such, there are less people who experience a “median bias” and subsequently less people for which the
treatment could correct their existing misperceptions.

C. How these findings relate to previous studies

The regularity of our findings across a diverse range of countries should be considered when assessing how they relate to previous studies. The only other study that directly tests the hypotheses in this paper, by Cruces, Perez-Truglia and Tetaz (2013), provides evidence that when people are told they are relatively poorer than they thought they become more supportive of redistribution. The difference in results between their survey experiment and our study could be due to a range of factors such as differences in location or the use of a household survey as opposed to an online survey. Our study is based upon representative samples of the population with internet access in a diverse set of 10 countries, whereas the sample in Cruces, Perez-Truglia and Tetaz (2013) is restricted to people living in one city in Argentina. In addition, we use an anonymous online survey as opposed to a household survey like Cruces, Perez-Truglia and Tetaz (2013), to minimize the risk of social desirability bias (when a respondent provides an interviewer with answers they think are more socially acceptable).

The notion of benchmarking that we articulate also helps to explain the findings of a recent study in the United States which shows that telling people they are richer than they thought in the global income distribution makes them more supportive of international redistribution (Nair 2018). Nair (2018) shows that most respondents to his survey in the United States thought they only had a slightly above average living standard compared to other people around the world and informing them that they were among some of the richest people on earth drastically changed their views. They became more supportive of foreign aid and more likely to provide money to charities operating in developing countries. This implies a similar weighting of people’s utility function to our study (i.e. $\beta > \gamma > 0$), whereby people are averse to inequality and are more concerned about the gap between their income and the poorest in society as opposed to the gap between their income and the richest in society. The key difference is that we focus on the poorest quintiles in the national income distribution, while Nair (2018) focuses on the richest quintiles in the global income distribution.

Our research bolsters findings from other studies on the elasticity of people’s preferences for redistribution (Kuziemko et al. 2015, Hauser and Norton 2017), which is that it is easier for information to alter people’s concerns about inequality than their desire for government-led redistribution. For example, Kuziemko et al. (2015) show that providing multiple pieces of information about inequality in the United States does not lead to greater support for redistribution⁶, even though it does have a large impact on people’s concern about inequality. We show a similar pattern, whereby even though we are able to detect effects on people’s concern about inequality from the treatment in most countries, this does not lead to statistically significant changes in their preferences for redistribution.

Our results also add considerably to the growing evidence base that suggests seminal

---

⁶The exception is in regards to support for the estate tax.
theories of preferences for redistribution should be modified to reflect the fact that most people do not have accurate information about the income distribution in their country (Gimpelson and Treisman 2018; Hauser and Norton 2017). Consistent with recent research in high-income countries, we show most relatively poor people do not realize they are near the bottom of the national income distribution and their perceived position in the distribution appears to be more closely aligned with their preferences for redistribution than their actual position in the distribution (Gimpelson and Treisman 2018; Hauser and Norton 2017; Kuhn 2015; Niehues 2014; Engelhardt and Wagener 2014). We extend these stylized facts from studies in high-income countries to a diverse group of middle-income countries. A practical implication of these findings is that policy makers who are interested in understanding people’s support for redistribution in their country should be as concerned (if not more so) about people’s perception of inequality as opposed to what is actually the case.

VI. Conclusion

This study makes a significant contribution by showing how one of the underlying assumptions of seminal theories of preferences for redistribution lacks empirical support in a diverse range of countries. In contrast to what theories assume, informing people they are relatively poorer than they thought reduced their concern about the gap between the rich and poor in their country. This effect was primarily driven by people who prefer low levels of inequality and actually belong to both the poorest and second poorest quintiles in their national income distribution. We illustrate that our results are consistent with the idea that people use their own living standard as a “benchmark” for what they consider acceptable for others. This phenomenon illustrates there are competing channels through which relatively poor people think about support for redistribution. Our findings are far more generalizable than other studies to date as we surveyed over 30,000 people from 10 countries that make up 30 per cent of the world’s population and 40 per cent of global GDP.

There are three directions which we believe are promising for future research on the topic of why relatively poor people are not more supportive of redistribution. Firstly, a deeper understanding could be developed about whether people’s preferences for redistribution are based on absolute, as opposed to relative, differences in incomes in society. Secondly, further survey experiments could examine what types of information, if any, would lead poorer people to become more supportive of redistribution. Finally, additional analysis could be conducted that explores what factors shape preferences for redistribution in developing countries.

VII. Tables and figures

Figure 1: Support for higher taxes on the wealthy to fund programs to help the poor

Note: The red line is the 45 degree line. As such when the data point is above the 45 degree line this means the share of relatively poor respondents is larger than the share of relatively rich respondents that support higher taxes on the wealthy to fund programs to help the poor. Relatively poor respondents have incomes below the median and relatively rich respondents have incomes above the median. The full wording of the question is: “What would you do to reduce the gap between the rich and poor in our country? Higher taxes on the wealthy and corporations to fund programs that help the poor OR Lower taxes on the wealthy and corporations to encourage investment and economic growth?”

This figure presents the results of a question about support for redistribution in a survey across 44 countries by PEW Research Center in 2014. Specifically, it shows the share of relatively rich and poor respondents in each country that prefer high taxes on the wealthy and corporations to fund programs to help the poor.

how income is CURRENTLY distributed between these groups.

[Graph showing income distribution]

**Figure 2b - Question about respondents’ preference for the level of inequality in the United States**

Regardless of how you previously answered, which best shows

how income SHOULD be distributed?

[Graph showing income distribution]

Note: The most unequal distribution option is based upon the actual level of income inequality in South Africa. This is followed by the distribution in the United States, the United Kingdom and the Netherlands. The most equal distribution options are more equitable than what exists in any country in the world. The preamble to the question was adjusted in each country. For example, in the United Kingdom the question stated “the total British population”, not “the total American population”.

Figure 2a shows the question that was asked about people’s views on the current level of inequality in the United States and Figure 2b shows the question that was asked about people’s preference for the level of inequality in the United States.
Figure 3 - Question about respondents’ perceived position in the national income distribution

Note: This question was asked immediately after the question shown in Figure 2.

This figure shows the question that was asked about people’s views on their perceived position in the national income distribution.
Figure 4 - Example of the information shown to respondents in the treatment group

Note: The treatment was tailored to the specific circumstances of each respondent based on which country they lived in and their reported household income in per capita terms.

This figure shows an example of the information provided to respondents in the treatment group in the United States who belonged to the second richest quintile.
Figure 5 - Perceived and preferred level of inequality in each country

Note: ES - Spain, IN - India, MA - Morocco, MX - Mexico, NG - Nigeria, NL - Netherlands, US - United States, ZA - South Africa, UK - United Kingdom. Australia is excluded because respondents were not asked prior to the treatment about their perceived and preferred level of inequality. 

Prefer High Inequality - Binary variable that takes the value of 1 if the respondent stated prior to the treatment they prefer high levels of inequality (defined as selecting the 1st or 2nd options in Figure 3). Perceive High Inequality - Binary variable that takes the value of 1 if the respondent stated prior to the treatment they prefer high levels of inequality (defined as selecting the 1st or 2nd options in Figure 2).

This figure shows that more than half of people in each country perceive high levels of inequality exist, but only around 20 percent of respondents prefer high inequality.
Figure 6: The perceived position in the national income distribution of respondents from the poorest two quintiles

Note: ES - Spain, IN - India, MA - Morocco, MX - Mexico, NG - Nigeria, NL - Netherlands, US - United States, ZA - South Africa, UK - United Kingdom, AU - Australia.

This figure shows the perceived position in the national income distribution of respondents from the poorest two quintiles in each country and it is based on answers to the question in Figure 4.
Figure 7: Share of respondents in the poorest two quintiles that prefer lower inequality, disaggregated by their perceived position in the distribution.

Note: The black lines at the end of each bar present the 95 per cent confidence intervals. ES - Spain, IN - India, MA - Morocco, MX - Mexico, NG - Nigeria, NL - Netherlands, US - United States, ZA - South Africa, UK - United Kingdom. Australia is excluded because respondents were not asked prior to the treatment about their preferred level of inequality.

This figure shows the share of respondents in the poorest two quintiles who prefer lower inequality than what they perceive to exist disaggregated by whether they perceive themselves to be in the poorest two quintiles or the middle and richest two quintiles in the national income distribution.
Figure 8: The impact of the treatment on respondents in the poorest two quintiles of the national income distribution that overestimated their position

Note: The results presented in the first panel are based on the share of respondents that agree the gap between the rich and poor is too large in their country and the results in the second panel are based on the share of respondents that agree the government is responsible for closing the gap between the rich and poor.

This figure provides a visual representation of the results for the main regressions in Table 3 by plotting the coefficients of the treatment dummies in each country for the outcomes of interest.
Figure 9: The impact of the treatment on the share of respondents that do not agree the gap between the rich and poor is too large in their country.

Note: ES - Spain, IN - India, MA - Morocco, MX - Mexico, NG - Nigeria, NL - Netherlands, US - United States, ZA - South Africa, UK - United Kingdom, AU - Australia.

This figure shows the share of respondents from the poorest two quintiles of the national income distribution who overestimated their position that do not agree the gap between the rich and poor is too large in their country.

*Note: According to Systemic Peace (Marshall and Elzinga-Marshall 2017) the state fragility score is a measure of both a country’s effectiveness and legitimacy in four performance dimensions: Security, Political, Economic, and Social, at the end of the year 2016 (the higher the score the more fragile the state). It is closely associated with its state capacity to manage conflict, make and implement public policy, and deliver essential services, and its systemic resilience in maintaining system coherence, cohesion, and quality of life, responding effectively to challenges and crises, and sustaining progressive development. The Individualism index is a measure of the extent that one’s personal identity is distinct from others, whereby a higher score means the country is more individualistic (Hofstede Insights 2020).*

This table presents background information about the level of income, inequality, government intervention in the economy, state fragility and the degree of individualism for each of the countries in this study.
Table 2: Questions about people’s concern about the gap between the rich and poor and whether they believe the government is responsible for closing the gap

<table>
<thead>
<tr>
<th>GAP</th>
<th>To what extent do you agree with the following statement “The gap between the rich and the poor in (COUNTRY X) is too large”? (Strongly Agree, Agree, Neither Agree or Disagree, Disagree, Strongly Disagree)</th>
</tr>
</thead>
<tbody>
<tr>
<td>RESPONSIBILITY</td>
<td>To what extent do you agree with the following statement “It is the responsibility of the government to reduce the gap between the rich and the poor”? (Strongly Agree, Agree, Neither Agree or Disagree, Disagree, Strongly Disagree)</td>
</tr>
</tbody>
</table>

*Note:* The name of the country where the survey took place was inserted where COUNTRY X is shown in the table. To analyze answers to these questions in our main regressions we create a dummy variable that takes on the value of 1 if the respondent agrees or strongly agrees with the statement and takes on the value of 0 otherwise.

This table presents the questions that were asked about respondents’ concern about inequality and support for redistribution. These questions are standard in the literature and were sourced directly from existing studies.

Note: ES - Spain, IN - India, MA - Morocco, MX - Mexico, NG - Nigeria, NL - Netherlands, US - United States, ZA - South Africa, UK - United Kingdom, AU - Australia. Gap too large - Binary variable that takes the value of 1 if the respondent agreed or strongly agreed the gap between the rich and poor in their country is too large. Government responsible - Binary variable that takes the value of 1 if the respondent agreed or strongly agreed the government is responsible for closing the gap between the rich and poor in their country.

This table presents the results of the regression analysis specified in equation 4, where the dependent variable either captures the share of respondents that agree the gap between the rich and poor is too large or the share of respondents that agree the government is responsible for closing the gap between the rich and poor.
Table 4: Effects of the treatment on relatively poor respondents who overestimated their position in the distribution pooled across all countries as well as pooled across middle-income and high-income countries

</table>

Note: MICs - Middle-income countries, HICs - High-income countries. Gap too large - Binary variable that takes the value of 1 if the respondent agreed or strongly agreed the gap between the rich and poor in their country is too large. Government responsible - Binary variable that takes the value of 1 if the respondent agreed or strongly agreed the government is responsible for closing the gap between the rich and poor in their country.

This table presents the results of pooled OLS regressions with country fixed effects, where the dependent variable either captures the share of respondents that agree the gap between the rich and poor is too large or the share of respondents that agree the government is responsible for closing the gap between the rich and poor. The first column presents the results of this analysis for all countries, the second column presents the results of this analysis for middle-income countries (India, Mexico, Morocco, Nigeria and Mexico) and the third column presents the results of this analysis for high-income countries (Australia, Netherlands, Spain, the United Kingdom and the United States).
